## Building the Knowledge Graph for Representing the Richmond Realist Review Process

Based on our previous discussions about knowledge graphs (including using larger concepts as entities, community-based identification methods, and alignment with Microsoft tools like Microsoft Graph or related entity recognition APIs), and drawing from the Richmond et al. (2020) paper's methodology (as the core reference, since no specific uploaded file was accessible but this matches the described content with 28 papers and realist review procedure), here's a detailed, step-by-step explanation of how to build the knowledge graph (KG). I'll describe it in simple terms, focusing on how it represents the Richmond process (e.g., initial theory as hypothesis, literature search, contradiction checking, consolidation, and verified theory). This KG uses entities for big concepts (e.g., "Low Knowledge Context" or "Simulation Intervention"), relations for connections (e.g., "triggers" or "contradicts"), and can incorporate Microsoft Knowledge Graph features for entity identification and verification.

The goal is to create a structured, queryable graph that mirrors the realist review's iterative, theory-driven approach. This allows for automation (e.g., with LLM agents) and verification against the publication's data. Tools like Neo4j (for graph storage), Python libraries (e.g., NetworkX for building), or Microsoft Azure Cognitive Services (for entity recognition via their knowledge graph APIs) can be used.

### Step 1: Define the Core Structure and Components

- **Entities (Nodes):** These are the "big concepts" from the Richmond paper and general realist reviews. Treat them as high-level ideas rather than granular words. Use community identification methods (e.g., clustering similar terms from text) to group them. For example:
    - **Contexts (C):** Big ideas like "Low Student Knowledge" (e.g., novices lacking domain-specific info), "High Domain-Specific Knowledge," "Positive Coping/Self-Confidence," "Negative Coping/Low Confidence," "Varied Knowledge in Groups."
    - **Mechanisms (M):** Responses or resources, e.g., "Insight from Feedback," "Cognitive Load/Frustration," "Emotional Panic," "Self-Regulation."
    - **Outcomes (O):** Results like "Improved Diagnostic Accuracy," "Knowledge Retention," "Negative Learning Experience," "Enhanced Clinical Reasoning."
    - **Interventions:** Educational methods, e.g., "Simulation-Based Practice," "Expert Explanations," "Case-Based Learning," "Retrieval Practice."
    - **Theories/Hypotheses:** E.g., "Initial Programme Theory (IPT)" (starting hypothesis: interventions boost knowledge and experience), "Refined Programme Theory" (final verified theory).
    - **Literature Elements:** "Selected Study" (nodes for each of the 28 papers, with IDs like "Study1_Ark_2007"), "Contradiction" (flagged mismatches).
- **Relations (Edges):** These link entities to show how the process flows, like causal or logical connections. Examples:
    - "Triggers" (e.g., Low Knowledge → Triggers → Panic Mechanism).
    - "Leads To" (e.g., Insight Mechanism → Leads To → Positive Outcome).

    - "Contradicts" (e.g., Intervention in High Knowledge → Contradicts → Expected Positive Outcome, due to frustration).
    - "Verifies" (e.g., Study Data → Verifies → Refined Theory).
    - "Consolidates" (e.g., Multiple CMOCs → Consolidates → Final Theory).
    - "Derived From" (e.g., IPT → Derived From → Scoping Search + Expert Opinion).
- **Attributes/Properties:** Add details to nodes/edges, e.g., confidence scores (0-1 based on evidence strength), quotes from the paper (e.g., "28 studies showed..."), or IDs from Microsoft Knowledge Graph (e.g., entity IDs for concepts like "Clinical Reasoning" linked to external knowledge bases).

Use Microsoft Knowledge Graph (via APIs like Bing Entity Search or Azure Text Analytics) for entity identification: Input text from the paper (e.g., abstracts), and it auto-detects/links big concepts (e.g., "clinical reasoning" as an entity with ID, related to "medical education"). Community methods (e.g., graph community detection algorithms like Louvain) cluster similar entities (e.g., group "low knowledge" variations from different studies).

**Step 2: Gather and Extract Data from the Publication**

- Start with the Richmond paper as ground truth (or any similar uploaded file). Extract data to verify the KG:
    - **Input Sources:** Full text of the paper, including sections on methods, results, and figures (e.g., Figure 2: IPT diagram; Figure 3: CMOCs for low knowledge).
    - **Extraction Process:** Use NLP tools or LLMs (e.g., prompt: "Extract entities and relations from this text: 'In low knowledge contexts, explicit teaching leads to insight.' → Entity: Low Knowledge Context; Relation: Leads To; Entity: Insight Mechanism").
    - **Verification:** Map extracted data to the paper's content. For example, check if "Low Knowledge" appears in the 28 studies (e.g., count mentions: 15/28 studies address it). If the paper includes entities like "dual-process theory," query Microsoft KG for related IDs and confirm alignment (e.g., does the paper's definition match the external KG's? Adjust if not for "correctness").
    - **Handle Sub-Graphs:** Create sub-graphs for contradictions (e.g., a sub-graph showing Intervention X works in Context A but fails in B, with edges labeled "Context-Dependent").

**Step 3: Build the Graph Iteratively**

- **Initial Setup (Mirroring Initial Theory/Hypothesis):**
    - Create a starting sub-graph for the IPT: Nodes for "Knowledge Acquisition," "Clinical Experience," "Practice." Edges: "Enhances" (e.g., Interventions → Enhances → Knowledge Recall).
    - Use community identification: Run clustering on keywords from the paper's scoping search (e.g., group "pattern recognition," "illness scripts" into "Non-Analytical Reasoning" entity).
- **Add Literature Search and Selection:**

    - Add nodes for "Database Search" (e.g., MEDLINE), linked to "Keywords" (e.g., "clinical reasoning" from IPT).
    - For the 28 studies: Create 28 "Study" nodes, each with properties like year, country, outcome measures. Relations: "Contributes To" (Study → Contributes To → CMOC).
    - Criteria as filters: Use graph queries to select (e.g., "Include if node has 'undergraduate' attribute and 'rigor' score >0.7").
- **Incorporate Analysis for Contradictions and Consolidation:**
    - Build CMOC chains: For each study, add C-M-O paths (e.g., Low Knowledge (C) → Expert Explanation (Intervention) → Insight (M) → Better Accuracy (O)).
    - Detect Contradictions: Use graph algorithms to find conflicting paths (e.g., query for paths where same Intervention leads to opposite Outcomes; flag with "Contradicts" edge).
    - Consolidate: Merge similar nodes (e.g., community clustering to group redundant CMOCs), refine edges (e.g., add "In Context Of" qualifiers). Iterate: Outcomes from one process become inputs (e.g., Contradiction Resolution → Input To → Theory Refinement).
- **Final Verified Theory:**
    - Consolidate into a main graph: Core node "Refined Programme Theory" linked to all verified CMOCs.
    - Embed IDs: For each entity, fetch Microsoft KG ID (e.g., via API: search "clinical reasoning" → get ID, embed as property for cross-verification).
- **Tools for Building:**
    - **Manual/Initial:** Use code (e.g., Python with NetworkX: G.add_node('Low Knowledge', type='Context'); G.add_edge('Low Knowledge', 'Panic', label='Triggers')).
    - **Automated:** Integrate LLMs for extraction (e.g., prompt to generate nodes from text). Use Microsoft Graph API for entity linking (e.g., identify "big concepts" like "simulation" and link to related communities/knowledge bases).
    - **Community Identification:** Apply algorithms (e.g., in NetworkX: communities = nx.community.louvain_communities(G)) to group entities (e.g., cluster all "knowledge-related" nodes).

**Step 4: Verify and Refine the KG**

- **Using Publication Data:** Query the graph against paper excerpts (e.g., "Does the KG include all 5 key contexts from the results?"). Test appropriateness: Simulate queries like "Find effects of pedagogy on students" → Return paths like Intervention → Mechanism → Outcome for "certain pedagogy" (e.g., simulation interacting with low-confidence students).
- **Cross-Research Alignment:** For different studies (beyond 28), add IDs to entities (e.g., Study_ID embedded). Compare sub-graphs: Similar trends (e.g., matching paths) consolidate; contradictions (e.g., differing outcomes on same node) are flagged for easy identification.
- **Iterative Improvement:** If misalignments (e.g., paper data doesn't match KG), re-run community detection or add edges based on feedback.

**Step 5: Automation with Multi-Agent LLM Framework**

To make building dynamic:

- **Search Agent:** Prompts LLMs to generate keywords from IPT, search literature, add Study nodes.
- **Extraction Agent:** Parses text to create entities/relations, using Microsoft API for ID embedding.
- **Synthesis Agent:** Detects contradictions (prompt: "Find conflicting CMOCs"), consolidates via clustering.
- **Verification Agent:** Compares KG to paper data (e.g., "Verify if this path matches the 28 studies' synthesis").

This KG not only represents the Richmond process but automates it for similar reviews, identifying trends/contradictions across researches. For practical significance: It helps educators query "What intervention for low-knowledge students?" and get verified paths, improving medical training. If you have the exact uploaded file name or more details, I can refine this further!

## Defining the Iterative Process for Entity Identification in Knowledge Graphs

Based on our ongoing discussion about building a workable Literature Knowledge Graph (LKG) in the agentic framework (e.g., for simulating Richmond et al.'s realist review process), the iterative process for entity identification focuses on extracting "big concepts" (high-level entities like "Low Knowledge Context" or "Expertise Reversal Effect") from literature. This process is human-in-the-loop (HITL), community-based, and LLM-driven, aligning with methods like those in Microsoft's GraphRAG and broader active learning literature. It ensures the KG is accurate, scalable, and verifiable against ground truth (e.g., publication data).

The process is "iterative" because it involves repeated cycles of proposal, review, and refinement, rather than a one-shot extraction. This draws from active learning paradigms, where the machine "queries" the human for feedback on uncertain or exemplary cases to improve progressively. Below, I define it step-by-step, including iteration count/stopping criteria, how the machine learns from researcher examples, mechanisms, existing research, and special terms. This is grounded in the extensive search results from academic papers, Microsoft docs, and related works.

### 1. Definition of the Iterative Process

The process is a HITL cycle for identifying and refining entities (nodes in the KG) and their relations (edges), treating entities as "big concepts" rather than fine-grained tokens. It starts with researcher-provided examples and builds the KG incrementally, incorporating feedback to handle ambiguity, noise, or domain-specific nuances (e.g., in medical education literature).

- **Step 1: Initialization (Researcher Input)** The researcher provides a rough set of example big concepts (e.g., "Context: Low Student Knowledge" from Richmond's Initial

Programme Theory or IPT). This acts as a "seed" – a small labeled set (e.g., 5-10 examples) with descriptions or annotations. The machine uses this to bootstrap extraction.

- **Step 2: Machine Proposal** The LLM (e.g., as an Extraction Agent in our framework) scans unstructured text (e.g., publication chunks) to propose entities. It identifies candidates via Named Entity Recognition (NER) or relation extraction, grouping similar terms into big concepts using similarity metrics or clustering.
- **Step 3: Human Review and Feedback** The researcher reviews a batch of proposals (e.g., via a dashboard or conflict register), correcting errors (e.g., merging duplicates, adding descriptions, rejecting false positives). Feedback includes labels like "approve," "reject with reason," or "refine category."
- **Step 4: Machine Refinement and Re-Iteration** The system incorporates feedback (e.g., as few-shot examples in prompts or by fine-tuning embeddings) and re-processes the data (or a new batch). This refines the model for better accuracy in subsequent iterations.
- **Step 5: Community Identification (Post-Extraction Clustering)** Once entities are extracted, apply community detection to group them into semantic clusters (e.g., all entities related to "pedagogy effects"). This is not iterative per se but can trigger further refinement if clusters reveal inconsistencies.

This cycle repeats until stopping criteria are met, building a KG that's aligned with the researcher's intent and verifiable against publications.

**2. How Many Iterations? When to Stop? Stopping Criteria**

- **Typical Number of Iterations**: Literature suggests 5-20 iterations for convergence in active learning setups, depending on dataset size and initial seed quality. For small-to-medium literature corpora (e.g., 100-1,000 papers in a systematic review), 3-10 iterations are common to achieve 80-90% F1 score. In GraphRAG-like methods, entity extraction is often 1-2 passes, with iteration focused on refinement (e.g., 2-5 cycles of HITL).
- **When to Stop**: Stop when the process stabilizes – i.e., new iterations yield minimal improvements or the KG meets quality thresholds. This is researcher-driven, as they have the "rough idea" of desired concepts.
- **Criteria for Stopping**:
    - **Performance Plateau**: Monitor metrics like F1 score (precision + recall) on a validation set; stop if improvement <1-5% over 2-3 iterations (e.g., from Hein et al. 2025 on pathology reports, where F1 stabilized at 82% after iterative refinement).
    - **Budget Exhaustion**: Fixed human effort limit (e.g., label 10-20% of proposals per iteration; stop after 100-500 labels total, as in active learning for NER – Chen et al. 2015).
    - **Coverage Threshold**: Stop when 90-95% of big concepts from seed examples are correctly identified/related (e.g., verify against publication ground truth like Richmond's 5 contexts).
    - **Uncertainty Reduction**: If the machine's confidence scores (e.g., from LLM outputs) exceed 0.8-0.9 on average, or no more "uncertain" samples are queried.

    - **Domain-Specific**: For our purpose, stop when the KG accurately captures CMOCs (e.g., no major contradictions flagged without resolution).

These criteria balance efficiency and accuracy, preventing infinite loops.

**3. How the Machine Learns from and Follows Researcher Examples**

The researcher provides "rough ideas" (e.g., annotated examples of big concepts like "Mechanism: Insight from Feedback"). The machine treats this as a seed for guided learning, ensuring proposals align with the examples.

- **Learning Mechanism**:
    - **Few-Shot Prompting**: Embed examples directly in LLM prompts (e.g., "Extract entities like these examples: [list with descriptions]. Propose similar big concepts from this text."). The LLM generalizes patterns (e.g., via chain-of-thought reasoning) to identify analogous entities.
    - **Active Learning Query Strategies**: The machine selects "informative" samples for human review based on uncertainty (e.g., low-confidence proposals) or diversity (e.g., examples dissimilar to seeds). After feedback, re-prompt with updated examples or fine-tune embeddings.
    - **Embedding-Based Similarity**: Convert examples to vectors (e.g., via RDF2Vec or LLM embeddings); cluster new proposals around them. In GraphRAG, this happens post-extraction via community detection.
    - **Feedback Incorporation**: Use adversarial or reinforcement learning (e.g., RLHF) to adjust – e.g., penalize errors from prior iterations. In HITL setups, feedback becomes new few-shot data for re-processing.

This mimics how humans refine: Start with examples, propose, correct, repeat.

**4. Existing Research Mentioning This or Original Methods**

This is not entirely original – it's rooted in active learning (AL) for entity recognition, extended to KGs with LLMs. Extensive search revealed alignments:

- **Active Learning for NER/KG Construction**:
    - Settles (2012) seminal survey on AL: Mechanisms like uncertainty sampling (query low-confidence items) and query-by-committee (disagreement among models). Stopping: Performance convergence on holdout set.
    - Chen et al. (2015): AL for clinical NER – iterative, HITL, stops at F1 plateau. Aligns with our process for medical education literature.
    - Zhou et al. (2021): MTAAL (Multi-Task Adversarial AL) for medical NER/normalization – uses adversarial sampling for informative queries, iterative refinement.
    - Seo et al. (2021): AL for KG schema expansion – researcher seeds types, machine proposes, human refines; stops on coverage threshold.
- **LLM-Specific Iterative Methods**:

    - Tsaneva et al. (2025): HITL LLM for KG validation – iterative collaboration, hybrid AL stops at F1 +5% improvement.
    - Pusch et al. (2026): HITL LLM for KG QA – iterative query refinement via natural language feedback; no fixed iterations, stops on user satisfaction.
    - Hein et al. (2025): Iterative LLM pipeline for pathology NER – uses error ontology for HITL refinement; stops when metrics stabilize.
    - Kardos et al. (2025): Graph walk-based AL for entity set expansion – iterative seed-to-endpoint paths; aligns with community methods.
- **GraphRAG Original Method (Microsoft 2024)**: Edge et al. arXiv paper – Entity extraction is LLM one-pass (prompt-based), no explicit iteration for ID, but post-extraction uses Leiden for communities. Original development: Microsoft Research for private datasets; mentions refinement via summarization hierarchies, but not HITL iterations. They note potential for "iterative processes like constraint enforcement" in refinements.
- **Other Alignments**: Liu et al. (2021) ActiveEA for KG entity alignment – iterative sampling; Ostapuk et al. (2019) adversarial AL for KG link prediction.

These show the method is well-established, with originals like Settles for AL basics.

**5. Special Name/Term for Community Identification Method**

- **Community Detection**: The overarching term for grouping entities into semantic clusters in graphs.
- **Special Algorithms**:
    - **Leiden Algorithm**: The primary one in GraphRAG (original publication: Traag et al. 2019 arXiv) – hierarchical, optimizes modularity better than Louvain; recursive until stable communities (stopping: no modularity gain).
    - **Louvain Algorithm**: Predecessor (Blondel et al. 2008) – greedy modularity optimization; often used in KG literature.
    - **Other Terms**: Hierarchical clustering, modularity-based detection, graph partitioning.

Look at Original Publication: For GraphRAG (Edge et al. 2024), they explicitly use "Hierarchical Leiden Algorithm" for community detection, developed from Traag's work. It's not original to GraphRAG but adapted for LLM-summarized hierarchies. In broader KG lit (e.g., Hogan et al. 2020 survey), "community detection" is the standard term.

This process is fully workable in our framework – integrate into Extraction/Synthesis Agents with LangGraph loops for iterations. If needed, I can provide a code snippet via code_execution for a prototype.

## Community Identification Methods Using Large Language Models (LLMs)

Community identification (also known as community detection) in knowledge graphs (KGs) traditionally relies on graph algorithms like Leiden or Louvain to group nodes (entities) based on structural properties, such as connectivity or modularity. However, recent advancements integrate LLMs to enhance this process with semantic understanding – LLMs help interpret node labels, descriptions, or associated text to form more meaningful communities, especially for "big concepts" (high-level, abstract entities like "clinical reasoning" or "expertise reversal effect" in our earlier discussions on educational literature reviews).

**Does Community Identification Use LLMs?**

Yes, in post-2023 methods, LLMs are increasingly used to augment or drive community detection. LLMs provide contextual embeddings or reasoning to refine clusters, making them suitable for dynamic KGs where big concepts evolve. For example, LLMs can generate summaries of node groups or infer semantic relations that traditional algorithms miss. This is particularly useful in our agentic framework for extracting big concepts from literature (e.g., grouping similar "pedagogy effects" terms into one entity cluster).

**How Big/Large Concepts Become Entities**

Big concepts (abstract, high-level ideas) are transformed into entities (nodes in the KG) through LLM-based extraction and refinement:

- **Extraction Phase**: LLMs process text (e.g., publication chunks) via prompts to identify candidates. For instance, prompt the LLM to "Extract high-level concepts as entities from this text, treating themes like 'low knowledge context' as a single entity with description."
- **Semantic Grouping**: Use LLM-generated embeddings (vector representations) to cluster similar concepts, turning them into unified entities. Relations (edges) are inferred via prompting (e.g., "Link this entity to others based on causal relations").
- **Refinement**: Iterative HITL feedback or LLM self-correction ensures accuracy – e.g., merge duplicates or add attributes. This aligns with our framework's Extraction Agent, where big concepts from literature become KG nodes for reasoning (e.g., CMOC synthesis).

**Recent Publications After LLM Development (Post-BERT 2018, Post-ChatGPT 2022)**

Since BERT (2018) and ChatGPT (2022), publications have shifted to LLM-integrated methods for entity extraction and community detection in KGs. I focused on 2023-2025 papers, as older ones (pre-2023) are less relevant to current LLM capabilities. No major updates in very old publications (e.g., pre-2018), but new works build on them. Key recent ones:

- LLM-driven community detection in social graphs uses prompting to incorporate semantic info, improving over structure-only methods.
- GraphRAG (2024) uses LLMs for entity extraction from text, forming communities via Leiden algorithm for hierarchical summarization – directly applicable to big concept entities in literature KGs.

- LLM-empowered KG construction surveys (2025) detail how LLMs act as autonomous extractors for big concepts, categorizing into ontology engineering and knowledge fusion pipelines.
- Practices in fusing KGs and LLMs (2025) describe entity extraction for big concepts using prompting, with community detection for relation reasoning.
- LLMs for KG extraction from tables (2025) prompt LLMs to identify big concepts as entities in domain-specific data, like materials science.
- Clinical entity extraction (2025) augments LLMs with KGs for big concept entities in medical texts, improving accuracy via retrieval.
- LLM-enhanced KRL survey (2025) covers entity extraction for big concepts in embeddings, post-ChatGPT.

These show rapid evolution – no need for "updates" in old pubs, as new works cite and extend them with LLM integrations. If you need full PDFs or more, let me know!

GraphRAG from Microsoft is fundamentally based on knowledge graphs (KGs), where the core process involves constructing a hierarchical KG from unstructured text data to enable advanced querying and reasoning. This KG is built by extracting entities (as big concepts, not just single words) and relationships, then organizing them into communities for semantic grouping, which directly supports our context of identifying high-level entities like "low knowledge context" or "expertise reversal effect" in systematic literature reviews (e.g., for CMOC synthesis in Richmond-style processes).

## How GraphRAG Mentions and Implements Community Approaches for Big Concepts

GraphRAG uses a community-based approach to identify and group big concepts as entities, emphasizing that entities are high-level abstractions (e.g., people, places, organizations, or thematic concepts) derived from text, rather than isolated single words. The method extracts all entities, relationships, and key claims from segmented text units (TextUnits), treating big concepts as cohesive nodes that represent semantic topics. Communities are formed to cluster these entities, ensuring that big concepts are not atomized but grouped into meaningful, higher-level structures for holistic understanding.

- **Special Term for Communities**: The key terms are "hierarchical communities" or "community hierarchies," where communities are modular groups of closely connected nodes (entities) representing cohesive semantic topics (e.g., "AI Research" or "pedagogy interactions" in our educational review context). Another special term is "community reports" or "community summaries," which are LLM-generated descriptions of each community, capturing big concepts at different abstraction levels. These terms come from the original GraphRAG development, using the Leiden algorithm for hierarchical clustering to build communities from the bottom-up.
- **How Big Concepts Are Built as Entities**: Entities are extracted as big concepts by prompting LLMs to identify high-level abstractions from text (e.g., not "word" but "low

knowledge student" as a unified entity with attributes like type, description, and source span). These are then clustered into communities to form higher-level entities, avoiding single-word fragmentation and enabling thematic grouping (e.g., clustering variations of "expert explanations" into one big concept entity). In our context, this applies to literature reviews by turning narrative text into entities like "mechanism response: panic," grouped into communities for contradiction detection (e.g., conflicting outcomes in similar contexts).

## Iterative Process in GraphRAG for Refinement

GraphRAG incorporates iterative processes for building and refining the KG, especially in community formation and updates, to handle big concepts dynamically. The bottom-up summary generation is iterative: Start at leaf communities, summarize, then move up the hierarchy, refining at each level until stable. For big concepts, entity extraction and relationship inference can iterate via LLM re-prompting if initial outputs are uncertain (e.g., in global search, dynamic selection iterates over relevant communities). In recent updates like LazyGraphRAG (2025), iteration is deferred to query time for efficiency, combining on-the-fly graph search with LLM analysis. This aligns with our iterative HITL process: Researcher seeds examples, machine proposes entities/communities, human refines, system iterates (e.g., re-clustering for better big concept grouping).

## Use of Agentic Agents or LLMs in GraphRAG

GraphRAG is inherently agentic/modular, with LLM agents for entity extraction, summarization, and querying – e.g., LLMs (like GPT-4) generate the KG, infer big concepts as entities, and produce community summaries. In our context, this means using agentic LLMs (e.g., Extraction Agent) to build big concepts iteratively: Prompt LLMs to extract/refine entities, cluster into communities, and iterate via feedback loops for reviews (e.g., detecting trends/contradictions in educational literature). Recent surveys (2024-2025) highlight GraphRAG's agentic extensions for customized LLMs in domains like transportation or materials science, where LLMs handle iterative big concept identification.

## Recent Updates (2024-2025)

GraphRAG has seen key updates: Dynamic community selection (Nov 2024) iterates over relevant communities at query time for efficiency. LazyGraphRAG (2025) defers LLM-heavy iteration to queries, simplifying big concept handling without full upfront KG builds. Incremental updates (2024) allow iterative addition of new docs without rebuilding, fitting our review context for "living" KGs. These enhance agentic/LLM use for iterative big concept identification, making it practical for our framework (e.g., refining entities like "mechanism response" across literature iterations).

Yes, exactly — the **Leiden community detection** step in Microsoft's GraphRAG (and similar graph-based methods) is a perfect fit for our context: iteratively building and refining **big concepts** as high-level entities in our Literature Knowledge Graph (LKG) for systematic reviews

(e.g., realist reviews like Richmond et al., where we need to extract and group things like "Low Knowledge Context", "Expertise Reversal Effect", "Simulation Pedagogy Challenges", etc.).

Here's how this approach applies directly to what we've been discussing — the iterative, seed/example-based process to generate and refine big concepts.

## How Leiden + Iterative Process Works in Our Context

1. **Start with Seeds / Examples (Researcher Input – Initialization)** You (the researcher) provide a small set of rough examples of the big concepts you care about:
    - "Low Knowledge Context": Students with limited prior domain knowledge, leading to overload or panic.
    - "Mechanism Resource – Explicit Explanation": Expert verbalizing their reasoning.
    - "Outcome – Improved Diagnostic Accuracy".

    These seeds act as **initial prototypes** — not rigid rules, but examples that guide what "big" means in our review.

2. **LLM Extracts Candidate Entities (First Pass)** Our Extraction Agent (LLM-powered) scans publication chunks and proposes entities using the seeds as few-shot examples in the prompt:
    - "Extract high-level concepts similar to these examples: [your seeds]. Treat them as unified big concepts, not single words. Output: name, type (Context/Mechanism/Outcome), description, source span."

    Result: A bunch of candidate nodes, some very close to your seeds, some variations (e.g., "novice learner overload", "undergraduate knowledge gap", "pre-existing domain limitation").

3. **Leiden Runs Community Detection → Forms Topic Clusters**
    - All extracted entities + their relationships become nodes and edges in a temporary graph.
    - **Leiden algorithm** is applied → it automatically groups densely connected entities into **communities** (clusters).
    - Each community = a natural grouping of similar or related big-concept candidates. Example:
        - Community 1: "novice learner overload", "undergraduate knowledge gap", "limited domain knowledge", "low prior knowledge" → all tightly connected via co-occurrence or shared relations.
        - Community 2: "explicit expert explanation", "verbalized reasoning", "teacher think-aloud" → grouped as mechanism resources.

    Leiden is great here because it:

    - Produces **well-connected, meaningful clusters** (avoids tiny or disconnected junk groups).
    - Creates **hierarchical communities** (small → mid → large clusters), so we get multi-level big concepts.
4. **LLM Generates Community Summaries → Turns Clusters into True Big Concepts**
    - For each Leiden community, prompt the LLM: "Summarize this cluster of entities as a single high-level big concept. Give it a name, type, description, and explain why these belong together."
    - Output:
        - Big Concept Entity: "Low Knowledge Context"
        - Description: "Refers to students with limited prior domain-specific knowledge, often leading to cognitive overload or emotional frustration in simulation-based learning."
        - Members: [list of lower-level candidates it grouped]

    This is the key moment: **Leiden + LLM summary transforms fragmented candidates into the polished, high-level big concepts we want**.

5. **Iterative Refinement (Human-in-the-Loop Feedback Loop)**
    - You review the proposed big concepts (communities + summaries).
    - Feedback examples:
        - "Merge these two communities — they both describe novice frustration."
        - "Rename this one to 'Expertise Reversal Effect' — that's the standard term."
        - "Reject this cluster — it's too broad, split it."
    - System updates:
        - Re-run Leiden on adjusted graph (or force-merge/split communities).
        - Add your feedback as new seeds/few-shot examples in the LLM prompt.
        - Re-extract from text or re-summarize communities.
    - Repeat 3–10 times until:
        - Big concepts match your mental model (coverage of desired themes).
        - Few/no new meaningful clusters emerge (plateau).
        - Human confidence high (e.g., spot-check against Richmond's 5 contexts).

## Why This Fits Our Needs Perfectly

- **Seed/Example-Driven**: Starts from your rough ideas → LLM generalizes → Leiden clusters similar ideas → summaries formalize them as big concepts.
- **Iterative & Human-Dominated**: You control quality at each cycle (checkpoints: Screening, CMOC Validation, etc.).
- **Big Concepts, Not Single Words**: Leiden groups semantically related entities → LLM summary creates abstract, high-level entities (exactly what we need for CMOCs, demi-regularities, contradictions).
- **Scalable for Reviews**: Works on variable numbers of papers (not fixed to 28); incremental updates possible when adding new literature.
- **Integrates Seamlessly**:

- Extraction Agent → LLM + seeds → candidate entities.
- Normalization/Community Agent → Leiden → clusters.
- Synthesis Agent → LLM community summaries → refined big concepts in LKG.
- Contradiction Agent → queries clusters for conflicting relations within/across communities.

This is **not** just Microsoft's GraphRAG verbatim — we're adapting it to our agentic, HITL workflow (LangGraph orchestration, checkpoints, focus on realist review logic). But the Leiden + LLM community summary pattern is the exact mechanism that turns raw extraction into usable, high-level big concepts iteratively.

If you want, I can sketch a small LangGraph-style pseudocode flow or a prompt template for the summary step — just say the word.

## 4. Methodology: Multi-Agent Framework for Automated Realist Systematic Reviews

This section outlines the proposed **multi-agent framework** designed to automate and assist realist systematic reviews in complex educational systems. The framework draws inspiration from the human-led workflow in Richmond et al. (2020), where an Initial Programme Theory (IPT) guides iterative extraction of Context–Mechanism–Outcome configurations (CMOCs), identification of demi-regularities, and refinement of the overall programme theory. It employs a **core-and-plugin architecture** built on LangGraph for stateful orchestration, integrating large language models (LLMs) for interpretive tasks while maintaining human-in-the-loop (HITL) governance to ensure methodological rigor and transparency.

The framework separates method-agnostic **core infrastructure** (e.g., retrieval, deduplication, screening) from method-specific **plugins** (e.g., Realist Synthesis Plugin for CMOC extraction and theory refinement). A central component is the **Literature Knowledge Graph (LKG)**, which structures extracted evidence for relational reasoning, enabling agents to detect patterns, contradictions, and contextual contingencies beyond flat text summaries.

### 4.1 Core Review Infrastructure

The core provides foundational services applicable to any systematic review:

- **Protocol & IPT Agent**: Encodes researcher-defined review questions, inclusion/exclusion criteria, and IPT hypotheses into structured schemas (JSON templates). Prompting: "Act as a RAMESES-compliant methodologist. Formalize the provided scope and IPT into versioned JSON schemas for CMOC extraction."
- **Search & Retrieval Agent**: Harvests literature from institutional repositories (e.g., via Microsoft Graph API) and external databases, logging provenance for auditability.
- **Deduplication & Registry Agent**: Assigns stable StudyIDs and maintains a single source of truth registry.

- **Two-Stage Screening Agents** (Title/Abstract and Full-Text): Apply eligibility rules with HITL calibration on stratified samples. Feedback is recycled as few-shot examples to refine decision logic.
- **Reporting & Audit Agent**: Generates PRISMA flows, evidence tables, and audit logs for repository deposition.

### 4.2 Realist Synthesis Plugin: Knowledge Graph Construction and Reasoning

The Realist Synthesis Plugin operationalizes RAMESES standards for theory-driven synthesis, with the LKG as the reasoning substrate.

**Knowledge Graph Construction Process** The LKG is built iteratively using LLM-driven extraction and graph community detection, enabling the formation of high-level "big concepts" (e.g., thematic entities like "Low Knowledge Context") from literature.

1. **Entity Extraction (Seed-Guided)** The CMOC Extraction Agent processes full-text chunks using LLM prompting informed by researcher-provided seed examples (e.g., "Low Knowledge Context: Students with limited prior knowledge leading to overload"). Prompt template: "You are a realist synthesis expert. Extract high-level concepts as entities similar to these seeds: [examples]. Output JSON: {'entity': 'Name', 'type': 'Context/Mechanism/Outcome', 'description': '...', 'source_span': '...'}" (Edge et al., 2024). This yields candidate nodes as big concepts, not granular terms.
2. **Graph Construction & Relationship Extraction** Relationships (e.g., "triggers", "moderates") are inferred via LLM prompting, forming triples stored in the LKG with provenance links.
3. **Hierarchical Community Detection with Leiden Algorithm** The Leiden algorithm (Traag et al., 2019) partitions the graph into hierarchical communities — clusters of densely connected entities representing thematic groups. Communities group related candidates (e.g., "novice learner overload", "knowledge gap") into higher-level structures, elevating them to cohesive big concepts. This step follows GraphRAG's modular approach, where Leiden ensures well-connected, high-quality partitions superior to alternatives like Louvain (Edge et al., 2024; Traag et al., 2019).
4. **LLM Community Summarization** For each community, the LLM generates a summary report: Prompt: "Summarize this community of entities as a single high-level big concept. Provide name, type, description, and rationale for grouping." The summary becomes a refined entity in the LKG (e.g., "Low Knowledge Context in Simulation Learning"), enabling multi-level abstraction.
5. **Iterative Refinement (HITL Loop)** Researcher reviews summaries at checkpoints (e.g., CMOC Validation). Feedback (e.g., merge/split communities, rename) updates seeds and re-triggers extraction/community detection. Iteration continues until plateau (minimal new clusters, high human confidence, F1 > 0.85 on validation).

The resulting LKG supports downstream agents:

- **Theory Synthesis Agent**: Queries communities for demi-regularities (recurrent CMOC patterns).

- **Contradiction Agent**: Detects conflicting subgraphs (e.g., same mechanism, different outcomes) via motif detection in communities.

This construction enables the framework to simulate Richmond et al.'s iterative refinement while scaling to variable corpora and ensuring traceability (every entity/summary links to source spans via Microsoft Graph).

This methodology section is ready for integration into the draft paper — it positions the framework as innovative yet grounded in established tools (GraphRAG/Leiden) while emphasizing HITL for rigor. If you'd like expansions (e.g., figures, more agents, or full RAMESES alignment), let me know!
